(Received 5 May 2005; revised 18 November 2005; accepted 22 November 2005)

In this study we assessed age-related differences in the perception and production of American English (AE) vowels by native Mandarin speakers as a function of the amount of exposure to the target language. Participants included three groups of native Mandarin speakers: 87 children, adolescents and young adults living in China, 77 recent arrivals who had lived in the U.S. for two years or less, and 54 past arrivals who had lived in the U.S. between three and five years. The latter two groups arrived in the U.S. between the ages of 7 and 44 years. Discrimination of six AE vowel pairs /i-/l/, /i-e/, /e-x/, /æ-/l/, /a-/l/, and /u-/l/ was assessed with a categorial AXB task. Production of the eight vowels /i/, /e/, /æ/, /æ/, /Λ/, /α/, /u/ was assessed with an immediate imitation task. Age-related differences in performance accuracy changed from an older-learner advantage among participants in China, to no age differences among recent arrivals, and to a younger-learner advantage among past arrivals. Performance on individual vowels and vowel contrasts indicated the influence of the Mandarin phonetic/phonological system. These findings support a combined environmental and L1 interference/transfer theory as an explanation of the long-term younger-learner advantage in mastering L2 phonology. © 2006 Acoustical Society of America. I. INTRODUCTION

In cross-language developmental studies of non-native speech learning, two primary research goals are to accurately document and explain developmental changes in the ability to learn new speech sounds. To address these goals, the current study investigated how age-related differences vary along one important dimension of learning, the amount of exposure to the target sounds.

Past research on age-related differences in non-native speech learning can be classified into two main categories:

a) A portion of this work was published in “Age differences in perceptual sensitivity to new speech sounds: The younger the better?” Proceedings of the 29th Boston University Conference on Language Development, Boston, November, 2004, and was presented in “Age differences in the perception and production of American English vowels by native Mandarin speakers.” Poster presentation at the 1st Acoustical Society of America Workshop on Second Language Speech Learning, Vancouver, Canada, May, 2005.

laboratory studies and immersion studies. In laboratory studies, participants live in their native country and have no immersion experience with the target language. Participants are exposed to the target speech sounds of a foreign language only in the study setting, usually a research laboratory. This approach allows the assessment of age differences at the initial encounter with the new sounds, and offers good control over the amount of exposure to these sounds. Laboratory studies, which have focused primarily on production, have yielded inconsistent findings. Findings from some studies support the notion of “the younger the better.” When imitating Spanish words, monolingual English-speaking 7 year olds were slightly but significantly more accurate than young adults (Cochrane and Sachs, 1979). Similar findings were obtained among a group of native English-speaking 5–15 year olds when imitating French and Armenian words and phrases (Tatha, Wood, and Loewenthal, 1981a). In contrast, findings from other studies support the notion of “the older
the better." The accuracy in imitating Dutch words increased linearly with age among native English speakers ranging in age from 7 years to young adulthood (Snow and Hoefnagel-Höhle, 1977). The ability to imitate French words and discriminate French-sound pairs also increased with age among English-speaking first to ninth graders (Politzer and Weiss, 1969).

Taking advantage of the immigration phenomenon, immersion studies have examined age-related differences exhibited by immigrants as they acquire a new language in the second language (L2)-speaking country. These studies investigate the relation between age of exposure to L2, usually indexed by age of arrival (AoA) in the L2-speaking country, and learners’ L2 speech perception and production abilities. Immersion studies can be conducted at different points in time along a wide spectrum of length of L2 immersion. Long-term immersion studies include L2 learners who have resided in the L2-speaking country for many years when their L2 proficiency supposedly has reached relative stability following massive L2 exposure. Short-term immersion studies include L2 learners at a more recent stage of L2 immersion. There is no clear cut division between short and long terms, as some studies adopt a five-year (e.g., Jia, Aaronson, and Wu, 2002) and others a ten-year criterion (e.g., Flege, Munro, and MacKay, 1995a).

Findings from long-term immersion studies have consistently shown that, when the length of residence in the L2 country being equal, younger arrivals obtain better L2 speech perception and production skills than older arrivals. The benefit of early arrival existed for the overall degree of perceived foreign accent by English L2 learners speaking various native languages (Asher and Garcia, 1969; Flege et al., 1995a; Oyama, 1976; Yeni-Komşhian, Flege, and Liu, 2000), and for the accuracy in the perception and production of American English (AE) vowels and consonants (Flege, MacKay, and Meador, 1999; Flege, Munro, and MacKay, 1995b; MacKay, Flege, Piske, and Schirru, 2001; Munro, Flege, and MacKay, 1996) by native Italian speakers. Such age-related differences in production exist at an even earlier point of L2 immersion, i.e., after about two to three years of L2 immersion (Fathman, 1975; Tatha, Wood, and Loewenthal, 1981b).

Different from long-term attainment and laboratory studies that examine the performance at the one-time point, longitudinal immersion studies track performance over time. Snow and Hoefnagel-Höhle (1977) studied native English speakers living in Holland ranging in age from three years to adulthood. At three time points with a four to five month interval, participants distinguished Dutch minimal pairs, as well as imitated and spontaneously produced Dutch words. Although there were no significant age-related differences for perception at any point, age-related differences in production changed with increasing immersion experience. At the first testing session, older children and adults did significantly better than younger children in pronouncing many vowels and consonants. At the second session, age differences in pronouncing most of the segments disappeared. At the third session, age differences became reversed, with younger children outperforming older children and adults.

More recently, Flege et al. (in press) studied 155 native Korean-speakers living in the U.S. and Canada. The child arrivals (AoA between 6–12 years) and adult arrivals (AoA between 21–35 years) were tested after 3–4 years and then at 5 years of residence in these countries. The adult arrivals were judged to speak English with a significantly stronger foreign accent than the child arrivals. In a subgroup of these participants (n=108), the ability to discriminate and imitate English vowels was examined. Child arrivals outperformed adult arrivals after both 3 and 5 years of residence on both perception and imitation (Tsukada et al., 2005). Similar to Snow and Hoefnagel-Höhle (1977), these two studies demonstrated a period of younger-learner advantage. Different from Snow and Hoefnagel-Höhle, these two studies did not observe a period of older-learner advantage. This is likely due to the fact that the time 1 of the Flege et al. and Tsukada et al. studies was already after 2 years of L2 immersion, when the adult advantage could well have already disappeared. Indeed, in a longitudinal study of native Japanese speakers’ perception and production of English consonants /l/, /l/, and /w/, adult arrivals performed significantly better than child arrivals after six months of L2 immersion. However, after a year, the trend was reversed (Aoyama et al., 2004).

In sum, the few existing longitudinal studies suggest that age-related differences may change with increasing L2 exposure. The extent to which a study can demonstrate the crossover pattern depends on the time point(s) selected for the study. In the beginning of L2 immersion, older learners may have an advantage in discriminating and producing non-native speech sounds. This advantage may persist in early years of L2 immersion, but disappear and become reversed later. The exact timetable of this crossover pattern may depend on which aspects of phonological skills are assessed and the difficulty level of the assessment tasks.

Three general theoretical accounts have been put forth to explain the robust early learner advantage found in long-term immersion studies: the Critical/Sensitive Period account, the L1 Transfer/Interference account, and the Environmental account. The Critical/Sensitive Period account postulates a genetically guided maturation of a domain specific language learning mechanism as the reason for the declining abilities to learn new speech sounds. That is, there is a “limit to the programming of new phonological rules at the cortical level” (Cochrane, 1980; pp. 332–333) due to factors outside the learning process (e.g., Patkowski, 1990; Scovel, 2000).

In contrast, the L1 Transfer/Interference account posits that “new processing activities are hampered by the strength of heavily utilized patterns or processing routines” (Cochrane, 1980; pp. 332–333) used in native language processing. This account has been represented by three models of cross-language speech perception, the Perceptual Assimilation Model (PAM) (Best, 1995), the Native Language Magnet Model (NLM) (Kuhl, 2000; Werker and Tese, 1999), and the Speech Learning Model (SLM) (Flege, 1995). The three models, with some nonoverlapping foci, converge on an emphasis on the role of prior L1 learning and use in L2 speech perception and production. According to PAM, non-native segments “tend to be perceived according to their similarities
to, and discrepancies with, the native segmental constellations that are in the closest proximity to them in native phonological space.” (Best, 1995, p. 193). As will be referred to in detail later, this model makes specific predictions about the relative difficulty with which particular non-native segments are perceived or produced, based on their relation to the native phonological system. NLM delineates the details as to how, as early as in their first year of life, infants form a complex perceptual network through which new speech sounds are perceived, or “filtered” (Kuhl, 2000; Werker and Tees, 1999). SLM focuses in part on explaining age-related differences in learning new speech sounds. According to SLM, the greater difficulties experienced by older individuals arise from the increasingly strong influence of L1 (Flege, 1995). More specifically, with increasing age, L1 phonetic categories exert stronger assimilation power on non-native speech sounds, making the establishment of new speech categories more difficult (Baker, Trofimovich, Mack, and Flege, 2002; Flege, 2003).

The Environmental account (Jia and Aaronson, 2003; Snow, 1983) has been developed to explain the younger-learner advantage in various aspects of L2 proficiency found in long-term attainment studies. According to this account, in the immigration setting, L2 learners of various ages are inherently at different levels of cognitive, social, and cultural maturation. Such variations expose early arrivals to a significantly richer L2 environment than late arrivals, and such environmental differences accumulate and lead to L2 proficiency differences.

The validity of these three accounts relies heavily on a more accurate description of age-related differences in L2 speech learning. If the age difference crossover pattern discussed earlier proves robust, all three theories need to address these related questions. Why are early arrivals better in the long run? Why do late arrivals initially have an advantage? Why does it take time for early arrivals to catch up with and eventually surpass late arrivals? Most previous studies have focused on a limited period of L2 exposure. This has prevented firm conclusions about the interaction between age-related differences and the amount of L2 exposure. Although we can summarize trends from different studies, their sampling of different language populations and use of different methods and designs weaken the conclusion. Therefore, to shed light on the validity of the theoretical accounts, it is important to conduct further research to capture the dynamic changes of age-related differences in L2 speech learning at different points of L2 immersion with diverse populations.

To examine the interaction of age and amount of exposure to the target language, the current study included three participant groups with different amounts of exposure to native-sounding AE. The first was a group of native Mandarin speakers (chronological age at time of study 7 to 20 years) living in the People’s Republic of China (hereinafter referred to as China) with no English immersion experiences. Age differences found in this group are not confounded by age-related language environment differences existing in immigrant populations (Jia and Aaronson, 2003). Further, from the perspective of immigration, these participants could be a potential group of immigrants on the first day of their arrival in the L2-speaking country. Their chronological age at the time of the study matched the AoA for immigrant L2 learners.

The study also included two groups of native Mandarin speakers who immigrated to the U.S. at various ages: recent arrivals with a length of U.S. residence of 2 years or less, and past arrivals with a length of U.S. residence between 3 and 5 years. Based on the previous research findings, we anticipated a crossover pattern of age differences among these three groups.

In the current study we focused on the perception and production of L2 vowels. Previous research has shown that many L2 learners have persistent problems with L2 vowels (e.g., Bohn and Flege, 1992; Strange et al., 1998). Vowel production properties (spectral and temporal) have been found to contribute to the intelligibility of L2 English produced by native Mandarin speakers (Rogers, 1997) and Japanese speakers (Kewley-Port, Akahane-Yamada, and Aikawa, 1996). The vowels selected in the current study also bear different relations to the L1 vowel space, and thus allowed us to test theories (e.g., PAM, SLM) that predict specific types of L1 influences on L2. The details of these vowels will be presented in Sec. II.

Non-native speech perception and production is influenced by speaker and contextual variability in the target language. In order to pinpoint the source of vowel perception and production problems, the current study minimized these variations by conducting the tasks under constrained processing conditions. The target vowels were read by only one speaker in one consonantial context to form nonsense words for discrimination and immediate imitation. To further reduce the processing demands, perception and production procedures that minimize the memory load were used. If participants have problems discriminating and imitating vowels in this highly structured, predictable, and controlled context, they would experience greater difficulties with these vowels when placed in longer speech units during speech communication. Thus, in the study we examined the initial sources of difficulties experienced by participants, as well as whether and in what ways age-related differences exist at this processing level.

II. METHOD

A. Participants

1. Native Mandarin speakers in China

Participants in China were 91 native Mandarin-speaking children, adolescents, and young adults from 7 to 20 years of age. There were 46 females and 45 males, fairly evenly distributed across the age span with about six participants in each age group. Born and raised in Beijing, all participants spoke Peking Mandarin. They were recruited from average quality elementary, middle, and high schools, and colleges in Beijing. Participants were reported by teachers to have average level academic performance. To minimize the participants’ exposure to native-sounding English, participants were from schools with no native-English speaking teachers and no extensive training in English listening. No participants had received private English lessons with native En-
glish speakers, and few had attended supplementary English classes outside of school. The number of years of English language instruction ranged from 0 to 11 years ($M=4.41$ year; SD=2.81), mostly beginning in the fourth (36.4%), third (22.70%), and first (28.40%) grades.

2. Native Mandarin speakers in the US

Participants in the U.S. were 131 native Mandarin speakers who immigrated to New York City (NYC) between 7 and 44 years of age and had lived in the U.S. for fewer than 5 years. They were divided into two subgroups according to their length of U.S. residence: 54 past arrivals who had lived in the U.S. for between 3 and 5 years, and 77 recent arrivals who had lived in the U.S. for two years or less (Table I). These two groups did not differ significantly in their age, AoA, and age of onset of English instruction. They were set apart by years of residence in the U.S., and consequently, years of education in the U.S. Participants were recruited from the Chinese communities in NYC through an advertisement in a Chinese newspaper. The majority ($n=99$) spoke Mandarin (75.57%) as their native dialect, 14 (10.69%) spoke Min dialect, 13 (9.92%) spoke Wu dialect, and 5 (3.82%) spoke Cantonese. All non-native Mandarin speakers were exposed to Mandarin from birth, and all started speaking Mandarin regularly in school before 9 years of age. Similar to participants in China, their exposure to native-sounding English before their arrival in the U.S. was minimal.

No hearing screening was conducted for participants in China or the U.S. However, all participants reported having normal hearing in a background questionnaire described later.

B. Stimulus materials

The AE vowel inventory can be described as including 11 nonrhotic monophthongal vowels differing in height (5 levels: high, mid-high, mid, mid-low, low) and position (front versus back). The front vowels are /i, e, æ, a/ and the back vowels are /u, ō, o, ɔ, ʌ, ɑ/, /a/. The mid vowels /e, ə/ are usually phonetically realized as diphthongal /eɪ, əʊ/ in stressed syllables, mid-low /ʌ/ is unrounded and centralized relative to mid-low rounded /ɔ/, and other vowels show some diphthongization in some dialects (Peterson and Barrey, 1952; Hillenbrand, Getty, Clark, and Wheeler, 1995). The duration of AE vowels also varies phonetically, with the four short vowels /i, e, õ, ʌ/ alternating with the seven long vowels /iː, eː, æː, əː, oː, ɔː, ɑː/ (Peterson and Lehiste, 1960).

C. Design and procedure

1. Perception

Perception accuracy was assessed using a categorial (name identity) AXB discrimination task. This task was chosen among several discrimination tasks because it avoids the possibility of an age-related criterion shift found in same-different judgment tasks (Beving and Eblen, 1973) and possible difficulties that young children may have in understanding the concepts of “same” and “different.” Further, an AXB task poses less memory and processing demands than the other two triplet formats (Oddity, ABX) because the middle target stimulus is next to both comparison stimuli (MacKain, Best, and Strange, 1981).

Each vowel pair was tested with 12 trials, 3 trials for each of the 4 possible position combinations (AAB, ABB, BAA, BBA). This resulted in 72 trials for the whole test (6 pairs × 4 position combinations × 3 trials). The 72 trials were presented in 6 blocks of 12 trials. Each vowel pair appeared twice in each block. The order of blocks and trials within each block were randomized across participants. Each of the three selected tokens of a vowel was used the same number of times. Vowel positions were also balanced within and across blocks. The two same vowels in each AXB triplet were always two physically different stimulus tokens. This allowed us to test categorial perception at the minimum level, though not to the full extent as no differences in speakers or consonantal context were included.

A block of 12 trials with five Mandarin vowels /i/, /y/, /a/, /u/ designed in exactly the same format was presented before the test to familiarize participants with the task as well as to screen participants. Participants who made three errors or more were allowed to proceed with and complete the entire study, but their data were not included in analyses. According to the above criterion, four participants in China (one 8-year-old, two 9-year-olds, and one 15-year-old) were excluded from data analyses, leaving 87 participants for this group.

The AXB task was conducted using specialized computer software (written by Bruno Tagliaferri) available in the Speech Acoustics and Phonetics Laboratory (SAPL) at the CUNY Graduate Center. Each stimulus triad was preceded by a tone presented 300 ms prior to the first stimulus. After listeners heard the three disyllables (ISI=500 ms), two boxes appeared on the screen. The left one read “1,” and the right box read “3.” Participants were instructed to click “1” if they decided that the middle disyllable sounded like the first one, and click “3” if the middle one sounded like the third one. Once the participants clicked “1” or “3,” the next trial was triggered, with a 1000 ms intertrial interval. The trial and test sessions together took between 10 and 15 min. After each block of 12 trials, participants were offered the choice to take a break, although no participant chose to do so. All participants were tested individually, listening to the stimuli through earphones with volume adjusted to a comfortable level for the individual.

Participants in China were tested in a quiet office in their schools in Beijing, on a 15-in. screen portable PC. Participants in U.S. were tested in a soundproof room in the CUNY laboratory, using a 19-in. screen desktop PC.

2. Production

Prior to the discrimination task, participants imitated each of the eight /dV-/p-/ stimuli (/dæp/, /deʊp/, /dɑp/, /dɒp/, /dɪp/, /dɪp/, /dɛp/, and /dʊp/) three times consecutively, each time immediately after hearing the target disyllable. The production tokens were directly recorded as digitized sound files (22.05 kHz, 16-bit resolution) and then normalized for peak amplitude using Sound Forge. The files were further processed for an identification task by native English speakers. The files were first sliced into separate sound files each with one disyllable. Then, the nontarget vowel in each disyllable was removed by deleting all portions of the signal following the beginning of the /p/ stop closure defined as the cessation of upper formant energy. The aim of the editing was to eliminate the potential distraction of the nontarget vowel from the focus on the target vowel. Finally, each file was duplicated so listeners heard each stimulus twice. The time interval between the repetitions was 1000 ms.

For the purposes of token and response choice selections, a pilot identification task was conducted. Three native English-speaking listeners with IPA knowledge heard all three tokens of each vowel produced by the Mandarin speakers in China. A total of 16 AE monophthongs and diphthongs were used as response choices. Among the three tokens produced for each vowel, the second token elicited the highest agreement rate among the judges, and also yielded the most consistent identification results with both the first and the third token. Therefore, to reduce the amount of testing time, only the second repetition of each vowel was selected for the final task. Further, four of the 16 response choices that were never chosen by any listener were eliminated from the final identification choices.

There were a large number of clipped sound files for the participants in China. To counter their tendency to speak softly during the recording, they were instructed to speak loud, risking some signals being clipped. The productions of 42 participants in China and 127 participants in the U.S. who had at least one good token of each vowel were used. This yielded 168/42×126) × 8 utterances. These utterances were blocked by speakers, with 8 trials in each block. The productions were divided into four sessions with an approximately equal number of blocks. Each session had similar proportions of tokens produced by speakers from each group (speakers in China, recent arrivals and past arrivals), age (for
speakers in China), AoA (for speakers in the U.S.), and gender. When presented to the listeners, the order of the blocks and trials within a block were all randomized separately for each listener.

The 1344 utterances (168 participants × 8 vowels) were presented to five native speakers of English with a mean age of 39.4 years. Three listeners grew up in NYC and spoke English with the local accent. The other two were raised in Chicago or New Jersey, but both were familiar with New York City accent. All had IPA knowledge but were not experienced phoneticians. All listeners reported normal hearing. They listened to the tokens individually in an IAC acoustic chamber using customized software (written by Bruno Tagliaferri) that controlled stimulus presentation and recorded responses to an Excel data form. They completed two sessions on each of two separate days with a brief break between sessions. Listeners heard the stimuli through headphones at a comfortable level. They were instructed to pay attention to the vowel in the syllable, and identify, among the 12 orthographic labels and IPA symbols (“/dip/,” “/diph/,” “/dip/,” “/diph/,” “/ dép/,” “/dèp/,” “/dęp/,” “/diph/,” “/dēp/,” “/dēp/,” “/dawp/,” “/dawp/,” “/dope/,” “/dopc/,” “/dúp/,” “/du̯p/,” “/dype/,” “/du̯p/”), the one that sounded closest (though maybe not identical) to the token just heard. Before the test, listeners completed five practice blocks of 40 trials (5 speakers × 8 tokens) to familiarize themselves with the task. For the five speakers whose productions were used for the practice blocks, one was a monolingual English speaker who produced the stimuli for the current study, four were native Mandarin speakers (one adult male, one adult female, one child male, and one child female). Their imitation of the nonsense disyllables were elicited in exactly the same condition as the formal participants. Responses to these practice trials were not included in the data analyses. All five native listeners identified all the tokens of the monolingual English speaker correctly. Due to dialect influences, two additional native English listeners each made one or two errors identifying the monolingual tokens. These two listeners did not proceed with the identification study.

3. Background questionnaire

After the production and perception sessions, all participants filled out a background questionnaire. The questionnaires for participants in China and NYC were not identical but had overlapping items. The common items included gender, birth date, birth place, places where participants had lived, and any known hearing and health problems. Participants in China, in addition, listed their current school grade, the grade that English instruction began, and the number of hours of English classes in each week. Participants in NYC provided information about their age when English language instruction began, and their age of arrival in the U.S. Children and adolescents living with their parents rated their mothers’ and fathers’ English speaking ability along a 1–7 point scale (1=cannot speak English at all; 7=speak English as fluently as a native English speaker). They also reported the percentage of time that their father, mother, and siblings spoke to them in English, and the percentage of time that they watched TV and videos in English. All the above items regarding parents’ English proficiency and language use were rated for every year that participants were in the US. The average English use in a situation across all the years of U.S. residence was calculated for use in the statistical analyses.

III. RESULTS

The results are organized into three sections: perception, production, and the relation between perception and production. For both perception and production, performance accuracy was compared among the groups and across the vowel pairs (perception) or vowels (production) using mixed Analyses of Variance. Age-related differences were examined within each group using bivariate correlations, and other predictive variables were also investigated using regression analyses. Correlation and regression analyses were chosen over age group analyses because the former treats age as a continuous variable and maximizes its variance. The relation between perception and production was examined at the individual level as indicated by correlations between performance on perception and production, and at the group level by the extent to which the rank order of vowel pair (or vowel) difficulties matched in perception and production. In all results of the Analyses of Variance (ANOVA) reported below, the effect size (ES) is indicated by eta-squared values ($\eta^2$).

A. Perception

1. Accuracy across groups and vowel pairs

Perception accuracy was indicated by the percentage of correct responses out of the total 72 trials (for total accuracy), or the 12 trials (for each vowel contrast). Performance accuracy for the total task and for each vowel pair was compared across three participant groups. All three groups performed well above chance level with over 70% accuracy for all contrasts (Table II). A mixed two-way 6 × 3 ANOVA was conducted, with the 6 vowel pairs as the within-subjects variable, and the three participant groups as the between-subjects variable. The results revealed a main effect of group, $F(2, 215) = 53.18$ ($\eta^2 = 0.33$), a main effect of pairs, $F(4, 862) = 101.98$ ($\eta^2 = 0.32$; with Greenhouse–Geisser correction of degrees of freedom), and an interaction between group and pairs, $F(8, 862) = 10.87$ ($\eta^2 = 0.09$; with Greenhouse–Geisser correction of degrees of freedom) (all $p < 0.001$).

The main group effect reflects differential performance across the three groups. Pairwise comparisons (with Bonferroni corrections) indicate that participants in China had significantly lower accuracy than the recent and past arrivals. To further examine the group effect for each vowel pair, separate one-way ANOVA was performed for the performance on individual vowel pairs. There was a significant effect of group for all vowel pairs, including /i-/ /e/ /i/, $F(2, 215) = 26.97$, /æ-/ /æ/, $F(2, 215) = 11.66$, /æ-/ /æ/, $F(2, 215) = 32.46$, /i/- /i/, $F(2, 215) = 43.25$, /e/- /æ/, $F(2, 215) = 32.77$, and /æ/-, $F(2, 215) = 8.29$ (all $p < 0.001$). Bonferroni post-hoc tests re-
revealed that, for all vowel pairs, both the recent and past arrival groups scored significantly higher than the China group, and there were no significant differences between the two immigrant groups, probably due to ceiling effects.

Regarding the main effect of pairs, pairwise comparisons (with Bonferroni corrections) revealed that scores (averaged across the three participant groups) on most pairs of vowel contrasts (except for /æ-æ/ and /i-ɪ/) were significantly different (all $p<0.001$). The interaction effect of group and pair indicates that the performance difference in pairs varied among the three groups. To further examine this effect, paired-sample $T$ tests were conducted separately for each participant group to compare the performance on each pair of vowel contrast. For the participants in China, only one difference between vowel contrasts (/i-ɪ/ vs. /æ-æ/) were not significant, and all other 14 pairs were significant (all $p<0.01$). For the recent arrivals, two difference scores (/i-ɪ/ vs. /u-ʊ/; /i-ɪ/ vs. /æ-æ/) were not significant. For the past arrivals, three difference scores (/i-ɪ/ vs. /u-ʊ/; /i-ɪ/ vs. /æ-æ/; /ɛ-æ/ vs. /æ-ʌ/) were not significant. In terms of the rank order of performance, the two most difficult pairs (/ɛ-æ/ and /æ-ʌ/) and the two easiest pairs (/i-ɪ/ and /u-ʊ/) were the same for all three groups. The difficulty order for two medium-level performance pairs (/i-ɪ/ and /æ-æ/) was the opposite for participants in China and the U.S.

### 2. Age differences

The age variable of interest is the age of L2 exposure. For recent and past arrivals, it was indicated by AoA in the L2-speaking country. For participants in China, it was indicated by chronological age at the time of the study, which coincides with AoA, as they could be regarded as a group of immigrants on their first day of arrival in the U.S. Participants in China showed significant positive correlations between age and performance on the total task ($r=0.51$, $p<0.001$) and on all the individual vowel contrasts ($r=0.39$, $p<0.001$ for /i-ɪ/, $r=0.38$, $p<0.001$ for /i-ɪ/, $r=0.37$, $p<0.001$ for /ɛ-æ/, $r=0.43$, $p<0.001$ for /æ-æ/, $r=0.41$, $p<0.001$ for /ɔ-ʌ/, and $r=0.28$, $p<0.01$ for /u-ʊ/), indicating that older participants, in general, achieved a higher level of accuracy (Fig. 1). However, recent arrivals showed no significant correlations between AoA and overall performance or individual vowel pairs. In contrast, past arrivals showed negative correlations between AoA and overall performance ($r=-0.41$, $p<0.01$), and two of the more difficult vowel contrasts ($r=-0.36$, $p<0.01$ for /æ-æ/, and $r=-0.40$, $p<0.01$ for /æ-ʌ/), a trend opposite that of the participants in China. That is, a younger AoA predicted significantly better performance on the task in general, and on the difficult vowel contrasts.

### 3. Other predictors

To pinpoint the unique predictive power of AoA, several other potential predictor variables of performance were also examined. For the participants in China with little variance in the English environment, the major variable was length of English instruction. Older participants had significantly more years of English instruction, $r=0.89$, $p<0.001$, and more years of English instruction predicted a better task performance, $r=0.48$, $p<0.001$. A partial correlation analysis was conducted to examine the unique contribution of chronological age (AoA in our definition) and length of English instruction. When the length of English instruction was partialed out, there was still a marginally significant relation between age and the total percentage correct, $r=0.19$, $p=0.07$. When age was partialed out, the correlation between years of English instruction and the total percent correct became nonsignificant ($r=0.07$, $p=0.50$).

The predictor variables for the two immigrant groups included the age that English instruction began, the length of U.S. residence, the length of U.S. education, parents’ English speaking abilities, and the percentage of English use in various situations. Bivariate correlations between total accuracy and all of these predictive variables were obtained for each

**FIG. 1. Scatter plot of age and total accuracy (percentage correct) for native Mandarin speakers in China ($n=87$; $r=0.51$, $p<0.001$).**
group. For recent arrivals, only one significant correlation emerged: those who had spoken more English with their friends tended to perform better on the task, \( r = 0.31, p < 0.01 \). For past arrivals, better performance on the task was associated with a younger age at which English instruction began, \( r = -0.55, p < 0.001 \), and more years of U.S. education, \( r = 0.40, p < 0.01 \), and better English speaking ability of mothers, \( r = 0.42, p < 0.05 \). To further detect the unique predictive power of the four significant predictors for past arrivals, a hierarchical regression analysis was conducted. An interaction between the group and vowel, \( F(1,1155) = 4.31 (p^2 = 0.05) \), with the Greenhouse–Geisser correction of degrees of freedom (all \( p < 0.001 \)).

The group effect reflects the finding that participants in China had a lower overall accuracy than both the recent and past arrivals. To further examine the group effect for each vowel, separate one-way ANOVA was performed for the individual vowel accuracy scores. There were significant group differences for /e/ \( F(2,165) = 28.82, p < 0.001 \), /æ/ \( F(2,165) = 9.0, p < 0.001 \), and for /u/ \( F(2,165) = 6.74, p < 0.01 \). Bonferroni post-hoc tests revealed that, for all three vowels, participants in China scored significantly lower than both the recent and past arrivals, whereas these two latter groups were not significantly different from each other.

The main effect of vowel reflects varying performance on the vowels. The performance ranged from 94.99% for /a/ to 49.27% for /u/. The interaction of group and vowel indicates that performance differences on vowels varied among the three groups. Visual inspection of Table IM shows that the two easiest vowels were /a/ and /æ/ for all three groups, and the hardest two were /e/ and /u/. The recent and past arrivals had similar rank orders except a switch between ranks 2 and 3, and a switch between ranks 4 and 5. However, participants in China produced five vowels with accuracy around the lower 50% range, making the rank order less meaningful.

### 2. Age differences

Participants in China showed a nonsignificant correlation between age and average accuracy on all vowels, \( r = 0.26, p = 0.10 \). However, significant positive correlations between age and accuracy existed for two vowels, /e/ \( r = 0.31, p < 0.01 \), and /æ/ \( r = 0.42, p < 0.01 \). For past arrivals, better performance on the task was associated with a younger age at which English instruction began, \( r = -0.55, p < 0.001 \), and more years of U.S. education, \( r = 0.40, p < 0.01 \), and better English speaking ability of mothers, \( r = 0.42, p < 0.05 \). To further detect the unique predictive power of the four significant predictors for past arrivals, a hierarchical regression analysis was conducted. An interaction between the group and vowel, \( F(1,1155) = 4.31 (p^2 = 0.05) \), with the Greenhouse–Geisser correction of degrees of freedom (all \( p < 0.001 \)).

The group effect reflects the finding that participants in China had a lower overall accuracy than both the recent and past arrivals. To further examine the group effect for each vowel, separate one-way ANOVA was performed for the individual vowel accuracy scores. There were significant group differences for /e/ \( F(2,165) = 28.82, p < 0.001 \), /æ/ \( F(2,165) = 9.0, p < 0.001 \), and for /u/ \( F(2,165) = 6.74, p < 0.01 \). Bonferroni post-hoc tests revealed that, for all three vowels, participants in China scored significantly lower than both the recent and past arrivals, whereas these two latter groups were not significantly different from each other.

The main effect of vowel reflects varying performance on the vowels. The performance ranged from 94.99% for /a/ to 49.27% for /u/. The interaction of group and vowel indicates that performance differences on vowels varied among the three groups. Visual inspection of Table III shows that the two easiest vowels were /a/ and /æ/ for all three groups, and the hardest two were /e/ and /u/. The recent and past arrivals had similar rank orders except a switch between ranks 2 and 3, and a switch between ranks 4 and 5. However, participants in China produced five vowels with accuracy around the lower 50% range, making the rank order less meaningful.

### 1. Accuracy across groups and vowels

In this part of the analysis, performance accuracy, indicated by percent correct scores for all vowels and for each vowel were compared across the three participant groups. There was a wide range of accuracy levels across the different vowels (Table III). A mixed two-way 8 (vowels) \times 3 (groups) ANOVA analysis revealed a main effect of group, \( F(2,165) = 14.36 (p^2 = 0.15) \), a main effect of vowel, \( F(6,1155) = 37.76 (ES = 0.19) \), with the Greenhouse–Geisser correction of degrees of freedom, and an interaction between the group and vowel, \( F(11,1155) = 4.31 (p^2 = 0.05) \), with the Greenhouse–Geisser correction of degrees of freedom (all \( p < 0.001 \)).

The group effect reflects the finding that participants in China had a lower overall accuracy than both the recent and past arrivals. To further examine the group effect for each vowel, separate one-way ANOVA was performed for the individual vowel accuracy scores. There were significant group differences for /e/ \( F(2,165) = 28.82, p < 0.001 \), /æ/ /u/ \( F(2,165) = 9.0, p < 0.001 \), and for /u/ \( F(2,165) = 6.74, p < 0.01 \). Bonferroni post-hoc tests revealed that, for all three vowels, participants in China scored significantly lower than both the recent and past arrivals, whereas these two latter groups were not significantly different from each other.

The main effect of vowel reflects varying performance on the vowels. The performance ranged from 94.99% for /a/ to 49.27% for /u/. The interaction of group and vowel indicates that performance differences on vowels varied among the three groups. Visual inspection of Table III shows that the two easiest vowels were /a/ and /æ/ for all three groups, and the hardest two were /e/ and /u/. The recent and past arrivals had similar rank orders except a switch between ranks 2 and 3, and a switch between ranks 4 and 5. However, participants in China produced five vowels with accuracy around the lower 50% range, making the rank order less meaningful.

### B. Production

The listeners showed high agreement rates on the produced vowel identity. Of the 1344 vowel tokens (168 participants \( \times \) 8 vowels), five listeners agreed on 617 (45.90%) of the tokens. Another 331 (24.63%) tokens elicited agreement by four listeners. No judge showed obvious divergence from the group. The agreement rate varied among the vowels, ranging from 94% for /a/ to 41.67% for /æ/ by at least four listeners. This indicates that disagreements among the listeners were more likely due to the ambiguity of the productions rather than to listener factors. Taking these findings into account, data across all listeners were pooled together for analyses.

The production data from 42 participants in China, 50 recent arrivals, and 76 past arrivals were analyzed for both accuracy and error patterns. For accuracy analyses, all responses were scored as either correct or incorrect. When the intended vowel by the speaker and the chosen vowel by the listener matched, the response was correct. For each speaker, a percent correct score for a vowel was the proportion of correct responses out of five tokens. The total percent correct for all eight vowels was the average of the percent correct scores for the eight vowels.
No significant correlation was found for the recent arrivals. For the past arrivals, performance on two vowels, /l/ \([r=−0.24, p < 0.05]\) and /æ/ \([r=−0.33, p < 0.01]\) showed significant negative correlation with AoA, a trend opposite that of the participants in China.

### 3. Error patterns

The overall error patterns were analyzed by creating confusion matrices for the three groups (Table IV). Responses were classified by the 8 target (intended) vowels contained in each of the /dVp/ utterances produced by participants, and by the 12 vowels given as the response alternatives. The numbers on a row indicate the percentage of participants who responded to the target vowel heard on L2 phonological acquisition. The findings add to a more
tern, being most often heard as /l/. In contrast, /æ/ showed a more diffuse confusion pattern, heard as /l/, /l/, or even /æ/. For both /l/ and /æ/, the immigrant groups showed considerable improvement in production accuracy.

### C. Relation between perception and production

The relation between perception and production at both the individual level and group level was examined. The individual level relation was assessed by correlating perception and production total accuracy scores for the 168 native Mandarin speakers with measurable production data. There were significant positive correlations between perception and production performance for all participants together \((r=0.50, p < 0.001)\), for the participants in China \((r=0.42, p < 0.001)\), and for the past arrivals \((r=0.46, p < 0.01)\). The correlation for the recent arrivals was lower \((r=0.25, p=0.08)\). The close to ceiling perception performance of the recent and past arrivals might have lowered the correlations.

At the group level, rank orders of difficulty in perception and production were compared (Table V). For production, we combined the performance for the eight vowels into the six vowel contrasts by obtaining the bidirectional confusion rates (summing up the percentage of time that one vowel was identified as the other for each pair) and ranking these numbers. For perception, we rank ordered the average perception correct scores for all the 168 participants who had production scores. The bivariate correlation of the two sets of ranked scores was marginally significant \((r=0.77, p=0.07)\).

### IV. DISCUSSION

In the current study we investigated how age-related differences in the perception and production of AE vowels changed with an increasing amount of AE exposure. We included three groups of native Mandarin speakers with varying amounts of L2 exposure: those with no L2 immersion experiences who represented a population of potential immigrants on their first day of arrival in the U.S., those with moderate L2 immersion experiences (in the U.S. for two years or less), and those with substantial L2 immersion experiences (in the U.S. for between three and five years). To assess the unique contribution of our focus variable, AoA, other potential predictor variables of L2 learning were also examined. The inclusion of AE vowels that bear different phonetic relations to Mandarin vowels permitted the investigation of the influence of L1 phonetic/phonological system on L2 phonological acquisition. The findings add to a more
accurate description of age-related differences in L2 phonological learning, and call for a more refined theoretical account of the phenomenon.

With increasing L2 use, age differences in performance accuracy changed from an older-learner advantage to a younger-learner advantage for both perception and production. For the participants in China with no L2 immersion experiences, an older chronological age predicted a significantly higher discrimination accuracy of all vowel contrasts and higher production accuracy of two difficult vowels. For the recent arrivals, AoA was not related to performance at all. For the past arrivals, a younger AoA predicted significantly better discrimination accuracy for three vowel contrasts, and better production accuracy for two vowels.

The interaction of age-related differences with the amount of L2 exposure is consistent with the earlier study that demonstrated this full crossover pattern (Snow and Hoefnagel-Höhle, 1977). Notably, the findings of the current study and that of Snow and Hoefnagel-Höhle were obtained from different language populations (Mandarin-English versus English-Dutch), with different time sampling methods (cross-sectional versus longitudinal), and different linguistic foci (vowel perception and production in nonsense syllables versus real word perception and production). These findings further strengthen the view that older learners (or later arrivals in the immigration setting) initially have an advantage over younger learners (or early arrivals in the immigration setting), but this advantage disappears and then becomes reversed over the course of L2 immersion.

In light of these findings, theories that address age-related differences in phonological learning must explain not only the long-term younger learner advantage (as is the traditional focus), but also the short-term older-learner advantage and the processes of change involved. Although all three theoretical accounts predict and explain the long-term younger learner advantage, they are not similarly powerful in explaining the age-related differences exhibited prior to a long-term time point.

The Critical/Sensitive period hypothesis faces a challenge to explain why the genetically preprogrammed advantage of younger learners takes time to exert its effect. In light of the current findings, the theory should at least specify that, whatever the advantage younger learners have in phonological learning, it does not include an immediate superiority in perceptual sensitivity to and production accuracy of new speech sounds. In addition, this theory needs to specify domain specific phonological learning mechanisms that favor children within a sensitive period, and that take effects cumulatively over time.

The Environmental theory is fully consistent with our findings of the changing age differences with increasing L2 immersion. According to this theory, early and late arrivals in the immigration setting experience different language environments. In a longitudinal study of native Mandarin speakers learning English in the U.S., Jia and Aaronson (2003) found that early arrivals were exposed to a significantly richer L2 environment than late arrivals. The richer L2 environment was not only indicated by a greater quantity of L2 exposure, but also by a higher quality of L2 exposure, such as the intensive and highly motivated use of L2 during interactions with peers and the dominant society culture. Such language environment differences can accumulate over the years of L2 immersion, and lead to proficiency advantages of early over late arrivals.

Three types of findings from the current and other studies support the Environmental account. First, consistent with findings from the longitudinal study (Jia and Aaronson, 2003), the current results indicated that a younger AoA was associated with significantly more L2 use with parents, siblings, and friends averaged over the years of L2 immersion. Second, if the younger-learner advantage arises from a richer L2 environment, an early age of exposure should not guarantee high proficiency if the L2 environment is not rich enough. Flege et al. (1999) found that among native Italian speakers who immigrated to Canada at a young age, those who used English more were significantly better in discriminating English vowels than those who used English less. Third, if a richer L2 environment benefits early learners, more L2 exposure should benefit all learners. In the current study, native Mandarin speakers of all ages made significant improvement in AE vowel perception and production through L2 immersion. Further, recent arrivals who used more English with their friends, and past arrivals whose mothers had higher English-speaking abilities, discriminated the AE vowel pairs more accurately than the others.

The L1 Transfer/Interference theory postulates that older L2 learners’ difficulty is due to their more developed abilities in L1. Although the L1 phonological system is acquired early in life, speech motor control (e.g., Kent, 1992) and perceptual representations (e.g., Valley and Flege, 1999) for L1 speech sounds develop gradually through childhood and into adolescence. Along with these developments, older children and adults become more likely to perceive and produce new speech sounds through the filter of their L1 phonological system. In comparison to their older counterparts, native Korean-speaking children were less likely to assign Korean vowel categories to English vowels, suggesting that “children’s L1 sound categories are less powerful attractors of L2 sounds than those of adults” (Baker et al., 2002, p. 41). Such an account should predict a younger-learner advantage from the beginning of L2 immersion. Therefore, findings of the initial older-learner advantage of the current study and others (e.g., Politzer and Weiss, 1969; Snow and Hoefnagel-Höhle, 1977) do not appear to be in line with this account. However, a possible explanation exists. In the beginning, the L1 interference/transfer effects among older learners are not significant enough to override the overall perceptual and performance advantage they have in an optimal processing situation. The phonetic features detected by older learners may not be utilized during on-line processing of speech (Flege, 2003), and thus not contribute to the growth of proficiency.

If a more established L1 system renders late learners at a disadvantage for L2 speech learning, we should also expect that the acquisition of L1 has an impact on any speakers of L1, regardless of the age. Therefore, our findings of specific
influences of the L1 vowel system on L2 vowel learning serves as indirect evidence for the L1 Transfer/Interference account. Difficulty rankings for perception of vowel contrasts and production of vowels were similar across the three participant groups. For perception, the order of difficulty closely reflected the hypothesized order based on both phonetic similarity and hypothesized perceptual assimilation patterns influenced by L1 vowel space (Best, 1995). In the two most difficult pairs /æ-ʌ/ and /æ-ɻ/, the two vowels involved in each do not have close counterparts in Mandarin (not including allophonic variations), and are close in vowel space. Larger acoustic distances (i.e., /æ-ɻ/) or the presence of one of the two vowels in Mandarin (i.e., /i-e', h-ɹ/) was associated with medium level performance. Similarly for vowel production, /ɹ, ɻ/, with no close Mandarin counterparts, showed symmetrical confusions. AE /ɻ, ɻ/ were also confused in production, although the confusions were asymmetrical favoring /ɻ/. The two vowels that had corresponding LI counterparts /i, u/ showed close to ceiling accuracy in intelligibility, even when produced by speakers with no L2 immersion experiences.

The current study yielded a positive correlation between perception and production at the individual and group levels. At the individual level, better perception performance significantly predicted better production performance. At the group level, the vowel contrasts that were harder to distinguish in the perception task also had the highest bidirectional confusion rate in production. Vowel contrasts that were better distinguished were also produced with greater accuracy. These findings are consistent with those in the literature. Flege and colleagues found similar positive correlations between English vowel intelligibility and discrimination among native speakers of various languages (Flege et al., 1997; 1999). For example, both native Korean and Mandarin speakers identified synthetic vowels along the bat-bet (/æ-ɻ/) and beat-bit (/i-ɹ/) continua differently from native English speakers, and produced the two vowels in a contrast with bidirectional confusion (Flege et al., 1997). We note that the nature of such a positive relation between perception and production is still controversial. According to SLM, accurate L2 production to a large extent relies on accurate perception, and thus, perception development should precede production (Flege, 1995; McAllister, Flege, and Piske, 2002). Other researchers emphasize the causal role of production in perception. For example, Japanese speakers' production of English /ɹ/ and /ɻ/ was more accurate than their perception (e.g., Sheldon and Strange, 1982). However, perceptual training on the /ɹ-ɻ/ contrast did lead to production improvement by Japanese speakers (Bradlow, Akahane-Yamada, Pisoni, and Tohkura, 1999). Notably, tasks measuring production and perception abilities may be inherently incommensurable (e.g., Flege, 1999; Tsukada et al., 2005). They can pose varying levels of processing demands by the choice of stimuli, tasks, and procedures. The current production task promoted optimal performance with minimal processing demands. Only one consonantal context was used, and productions were rated in terms of intelligibility rather than degree of foreign accent (the latter is more stringent than the former, as found in studies such as Munro et al., 1996). Given this, several of our findings are consistent with the predictions of the SLM that production abilities at least partially rely on perception abilities. First, some Mandarin speakers were able to distinguish some vowel pairs accurately but confused them in production, indicating that production indeed lagged behind perception. Second, perception abilities improved at a faster rate than production abilities.

There are several limitations of the current study that can be addressed by future research. First, we manipulated the length of L2 exposure cross-sectionally rather than longitudinally. Some aspects of the participants in China and those in the U.S. were not completely comparable, such as the testing environments and Chinese dialect backgrounds. Nevertheless, the incomparability between the groups would have mainly affected our interpretations of the between group differences, not the age trends within each group. Second, in order to access optimal performance, the current study minimized speaker and contextual variations of the stimuli as well as the processing demands of the tasks. Future research should increase the variations along these dimensions to more closely approximate “on-line” phonological processing and learning.

In summary, the current findings indicate that age and amount of L2 immersion jointly influenced learning, indicated by a dynamic change of age-related differences with increasing exposure to L2. These findings support a combined Environmental and L1 Interference/Transfer theory as an explanation for the long-term younger-learner advantage in mastering L2 phonology. With increasing age, the growing influence of L1 perception and production patterns, coupled with L2 input of lesser quantity and quality, leaves the long-term achievement in L2 phonology of most older arrivals behind that of the younger arrivals. Our findings also indicate that older learners have their unique advantages in non-native speech learning. Future research should investigate how the strengths and weaknesses of younger and older learners interact in the learning processes, and tailor L2 speech learning and training strategies to learners of all ages.

Research reported in this article was supported by a City University of New York collaborative grant (No. 80209-01-08) awarded to the first and second authors, and a grant from the National Institute of Health (SCORE/NICHD #41353-11-19/20) to the first author. We thank Alan Wu for collecting the data from participants in New York City. We are grateful to the following colleagues who offered methodological advice at various points of the project, or read drafts of the manuscript: Jim Jenkins, Richard Bock, Akiko Fuse, Anne Reid, Keith Happaney, Erika Levy, Kanea Nishi, Puisan Wang and Shari Berkowitz. We also thank Bruno Tagliaferri for his technical support.
In this article, immersion refers to the holistic setting of learning a second language, L2, in the immersion setting, both in and outside school. It carries a different meaning from the concept of immersion in education, which refers to L2 acquisition through natural contact with L2 outside school as opposed to classroom instruction.

The older learner advantage in perception is likely due to multiple factors. First, it is partially due to growth in language related speech perception abilities. Studies of auditory perception development have shown a significant growth in the perceptual sensitivity to elements of speech signals related to language, such as signal duration (e.g., Elfenbein, Small, and Davis, 1993; Jensen and Neff, 1993). Second, it is partially due to growth of perceptual sensitivity that is not specific to cross-language phonetic influence. Tsukada et al. (2005) found that monolingual English-speaking children scored significant lower than monolingual-English speaking adults in discriminating /æ-ʌ/, but not /æ-ɛ/, /i-ɪ/, and /ɛ-ɛ/). Third, it is partially due to more years of English education, as pertaining out years of English education reduced the significant growth trend to a marginally significant level. The older learner advantage is unlikely to be due to disadvantages of younger children to handle the tasks. Younger children passed the practice Mandarin trials in a similar proportion as older participants did. The task duration was only 10–15 min. Younger children performed equally well on the six blocks, showing no indication of attention decline.
